Review Questions

- Q1: how does RE, NFA, DFA relate to each other?

  L(RE) ≡ L(NFA) ≡ L(DFA)

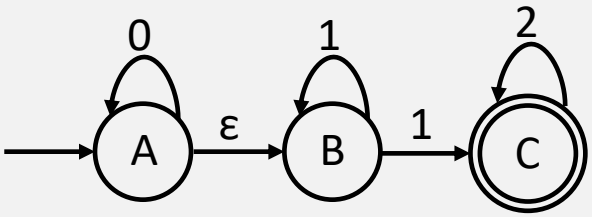
- Q2: NFA → DFA, time and space complexity

  Time: NFA-O(|X|*N^2) DFA-O(|X|)

  Space: NFA-O(N), DFA-O(2^N)

- Q3: RE of the NFA?

  0*1+2*

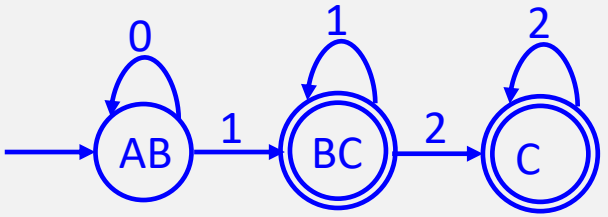


- Q4: start state of the equivalent DFA? ε-closure(A) = {A, B}

	0	1	2
AB	AB	BC	
BC		BC	C
C			C

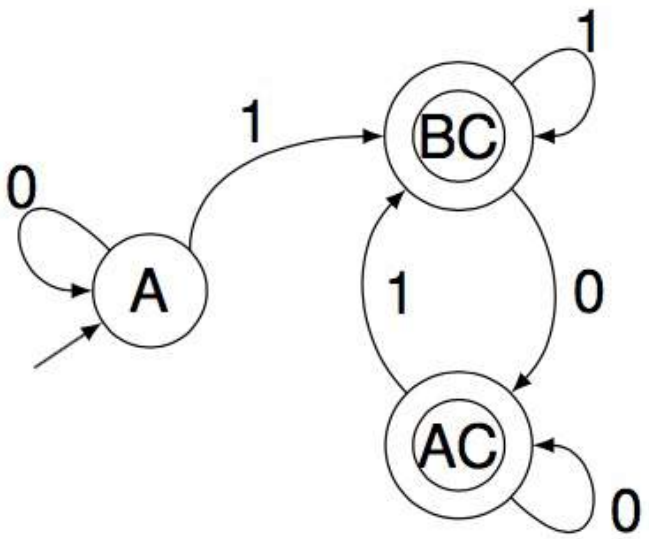
ε-closure(move({AB}, 0)) = ε-closure({A}) ⟹ {A, B}

ε-closure(move({AB}, 1)) = ε-closure({B,C}) ⟹ {B, C}



NFA → DFA: Minimization[最小化]

- Any DFA can be converted to its minimum-state equivalent DFA
  - Discover sets of equivalent states
  - Represent each such set with just one state
- Two states are equivalent if and only if[等价]:
  - $\forall \alpha \in \Sigma$, transitions on α lead to equivalent states
  - α-transitions to distinct sets ⇒ states must be in distinct sets



Initial: {A}, {BC, AC}

For {BC, AC} Initial sets: {non-accepting states}, {accepting states}

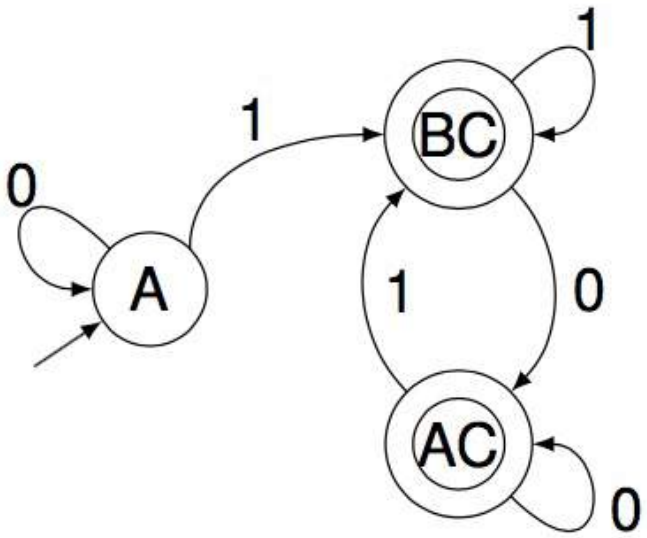
- BC on '0' → AC, AC on '0' → AC
- BC on '1' → BC, AC on '1' → BC
- No way to distinguish BC from AC on any string starting with '0' or '1'

Final: {A}, {BCAC}

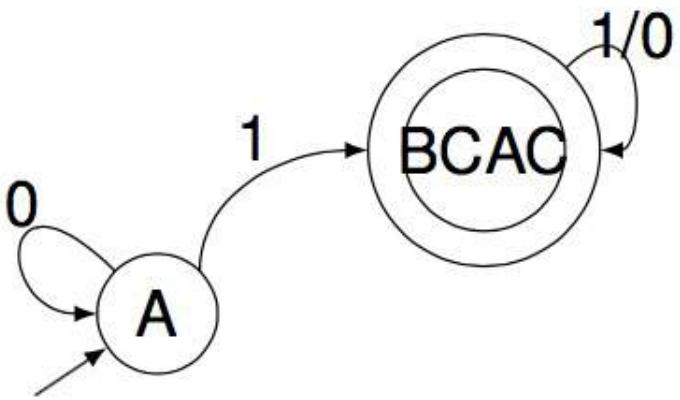
https://people.cs.umass.edu/~moss/610-slides/06.pdf

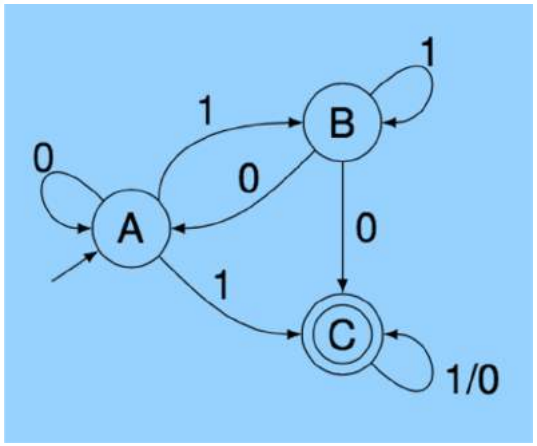
NFA → DFA: Minimization (cont.)

- States *BC* and *AC* do not need differentiation
  - Should be merged into one



Minimized





Minimization Algorithm

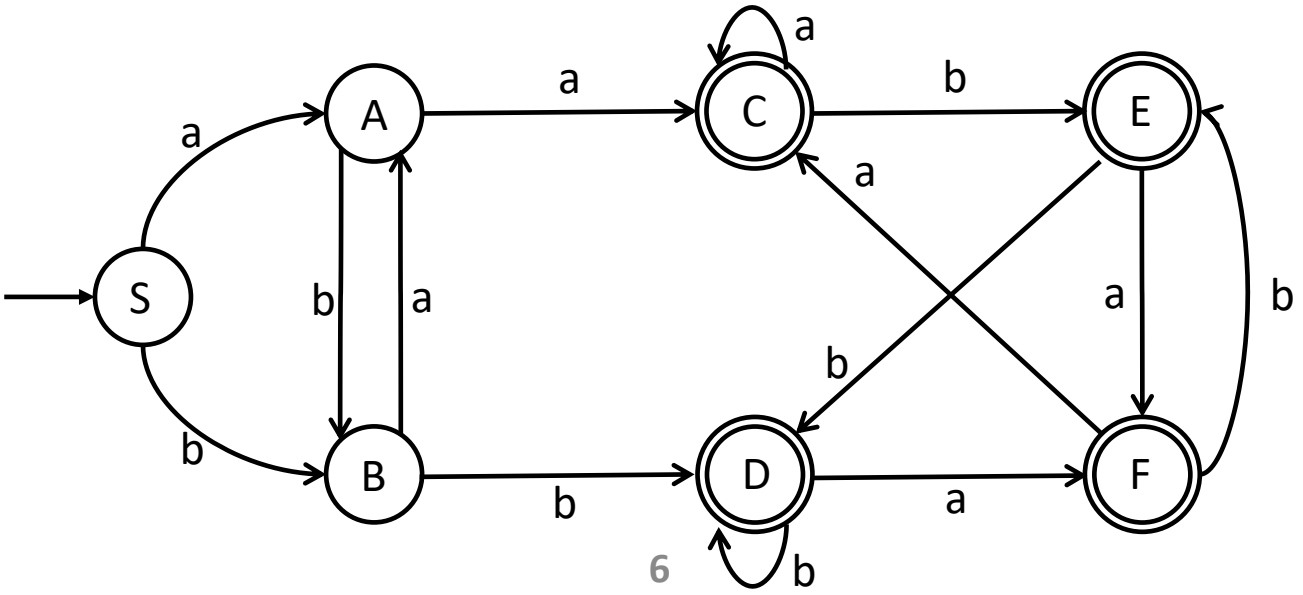
- The algorithm
  - Partitioning the states of a DFA into groups of states that cannot be distinguished (i.e., equivalent)[组内状态不可区分]
  - Each groups of states is then merged into a single state of the min-state DFA
- For a DFA（∑, S, n, F, δ）
  - The initial partition P_0, has two sets {F} and {S-F}
  - Splitting a set (i.e., partitioning a set ***s*** by input symbol α)
    - Assume q_a and $q_b \in$ ***s***, and $\delta(q_a, \alpha) = q_x$ and $\delta(q_b, \alpha) = q_y$
    - If q_x and q_y are not in the same set, then ***s*** must be split (i.e., α splits ***s***)
    - One state in the final DFA cannot have two transitions on α

```
P <- {F}, {S-F}
while (P is still changing)
  T <- { }
   for each state s ∈ P
      for each α ∈ Σ
         partition s by α into s1 and s2
         T <- T U s1 U s2
   if T ≠ P then
      P <- T
```

https://people.cs.umass.edu/~moss/610-slides/06.pdf

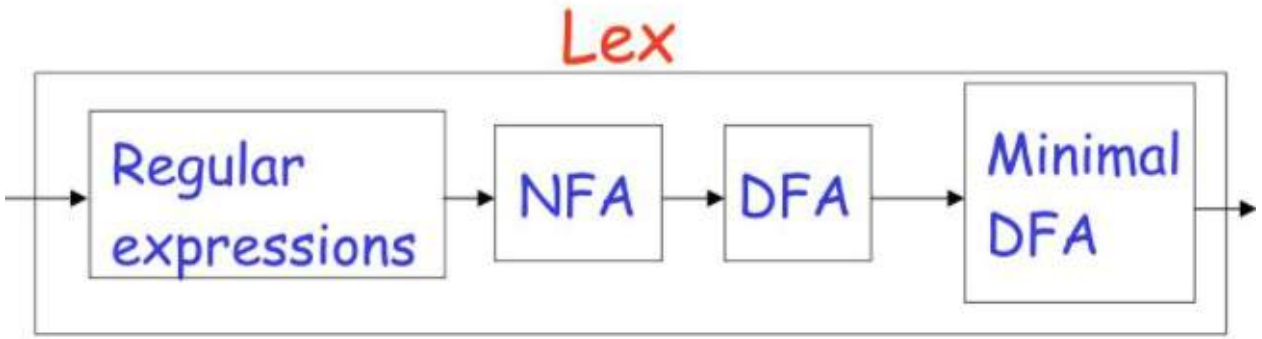
Example

- P0: s_1 = {S, A, B}, s_2 = {C, D, E, F}
- For s_1, further splits into {S}, {A}, {B}
  - a: S --> A ∈ s_1, A --> C ∈ s_2, B --> A ∈ s_1 $\Longrightarrow$ a distincts s_1
  - b: S --> B ∈ s_1, A --> B ∈ s_1, B --> D ∈ s_2 $\Longrightarrow$ b distincts s_1
- For s_2, all states are equivalent
  - a: C --> C ∈ s_2, D --> F ∈ s_2, E --> F ∈ s_2 , F --> C ∈ s_2 $\Longrightarrow$ a doesn't
  - b: C --> E ∈ s_2, D --> D ∈ s_2, E --> D ∈ s_2 , F --> E ∈ s_2 $\Longrightarrow$ b doesn't



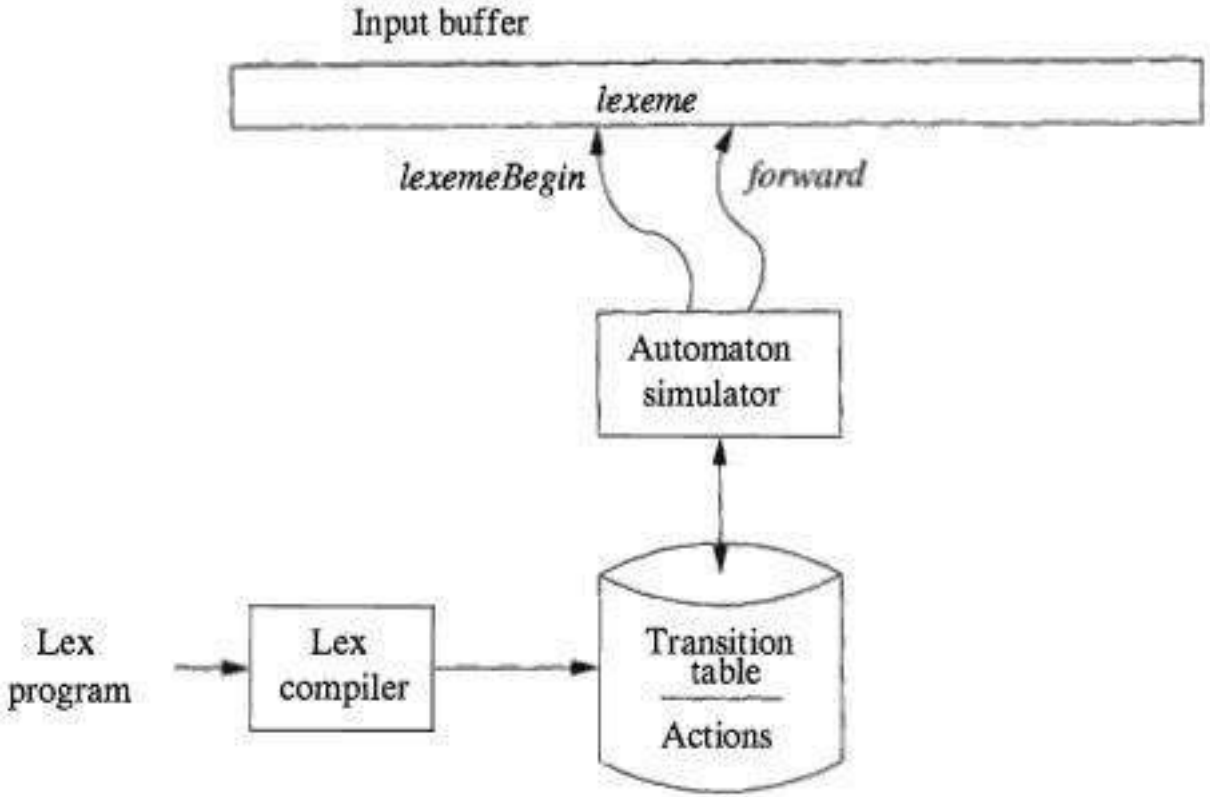
Implementation in Practice[实际实现]

- Lex: RE → NFA → DFA → Table
  - Converts regular expressions to NFA
  - Converts NFA to DFA
  - Performs DFA state minimization to reduce space
  - Generate the transition table from DFA
  - Performs table compression to further reduce space
- Most other automated lexers also choose DFA over NFA
  - Trade off space for speed



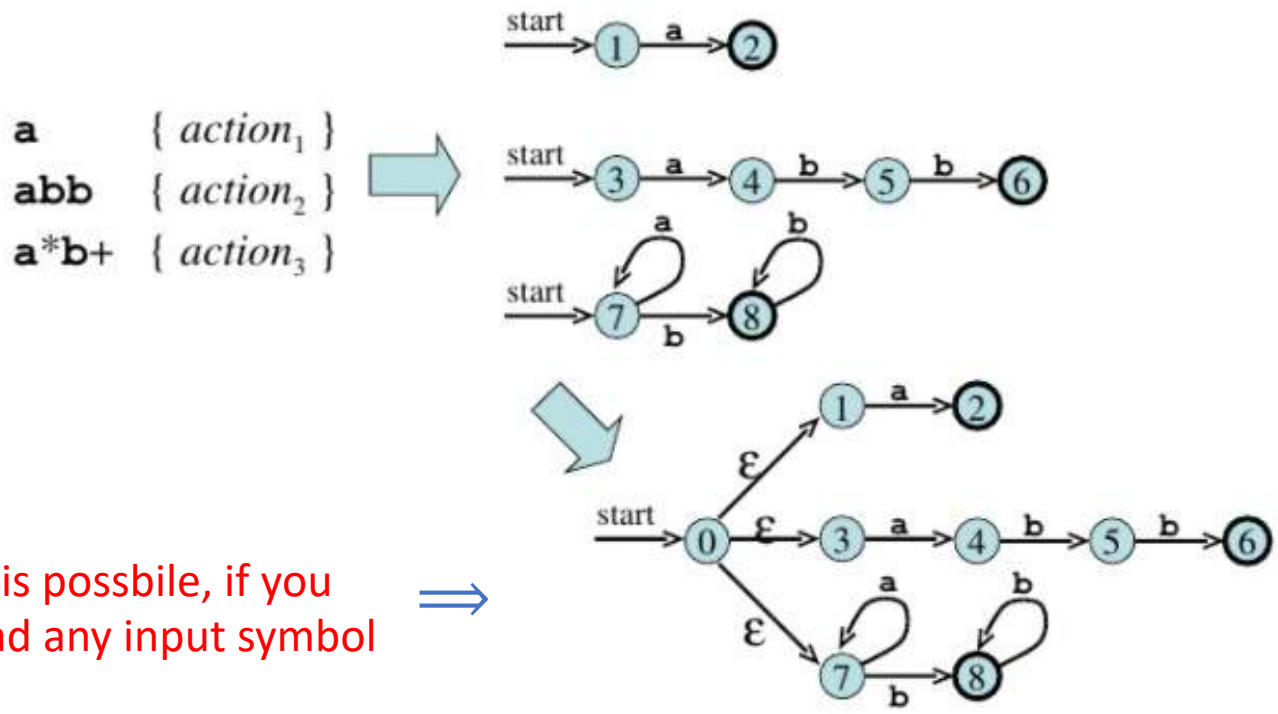
Lexical Analyzer Generated by Lex

- A Lex program is turned into a transition table and actions, which are used by a FA simulator
- Automaton recognizes matching any of the patterns



Lex: Example

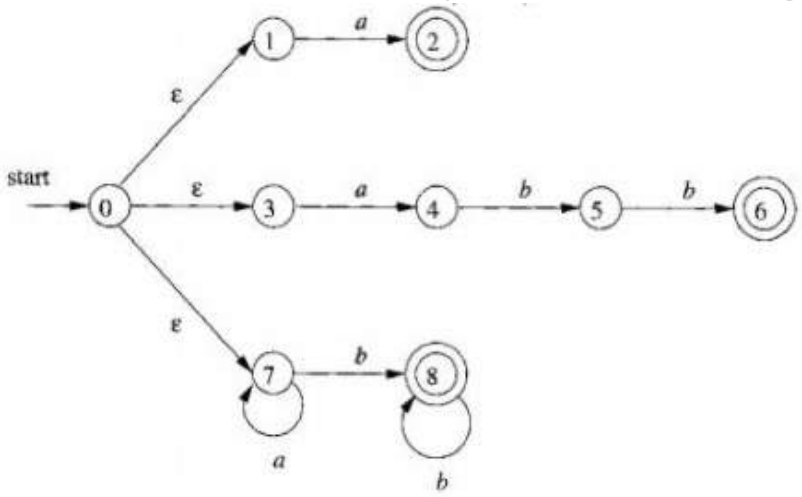
- Three patterns, three NFAs
- Combine three NFAs into a single NFA
  - Add start state 0 and ε-transitions

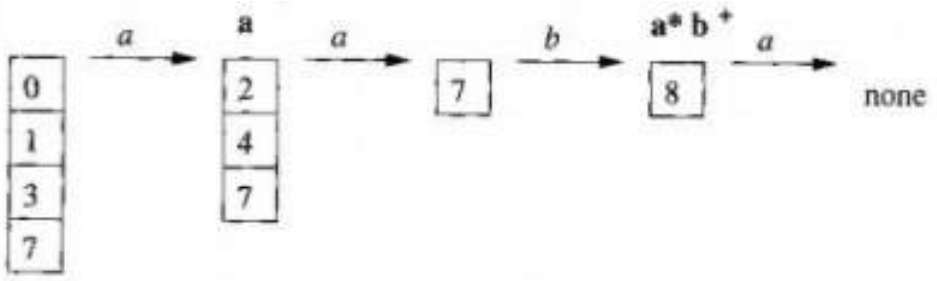


Any one is possbile, if you haven't read any input symbol ⟹

Lex: Example (cont.)

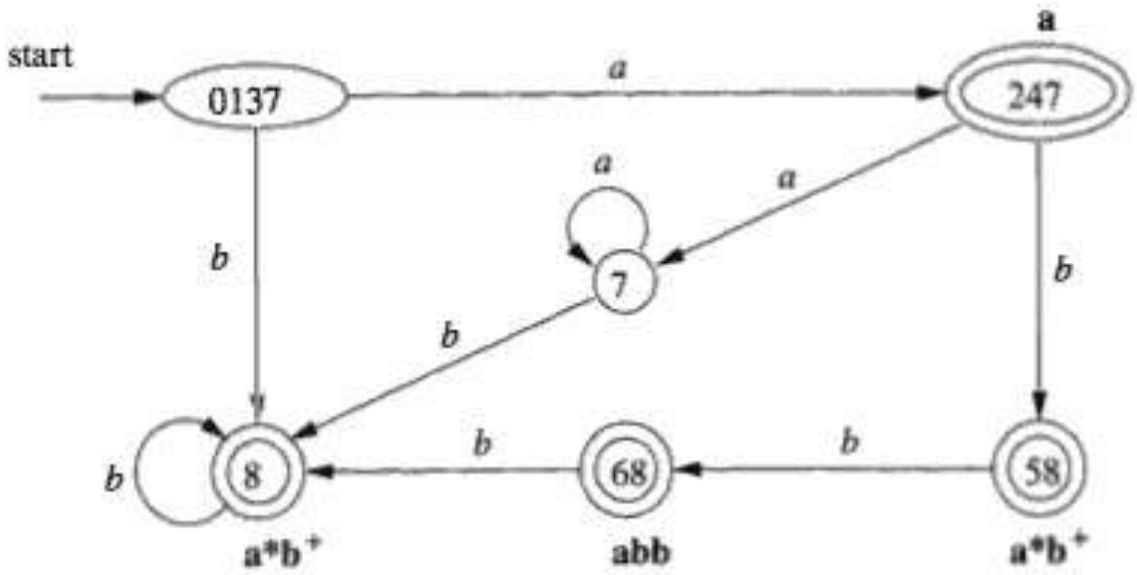
- NFA's for lexical analyzer
- Input: aaba
  - ε-closure(0) = {0, 1, 3, 7}
  - Empty states after reading the fourth input symbol
    - There are no transitions out of state 8
    - Back up, looking for a set of states that include an accepting state
  - State 8: a*b+ has been matched
    - Select aab as the lexeme, execute action$_3$
    - Return to parser indicating that token w/ pattern p_3=a*b+ has been found





Lex: Example (cont.)

- DFA's for lexical analyzer
- Input: abba
  - Sequence of states entered: 0137 → 247 → 58 → 68
  - At the final *a*, there is no transition out of state 68
    - 68 itself is an accepting state that reports pattern p_2 = abb



How Much Should We Match?[匹配多少]

- In general, find the longest match possible
  - We have seen examples
  - One more example: input string aabbb …
    - Have many prefixes that match the third pattern
    - Continue reading *b*'s until another *a* is met
    - Report the lexeme to be the intial *a*'s followed by as many *b*'s as there are
- If same length, rule appearing first takes precedence
  - String *abb* matches both the second and third
  - We consider it as a lexeme for p_2, since that pattern listed first

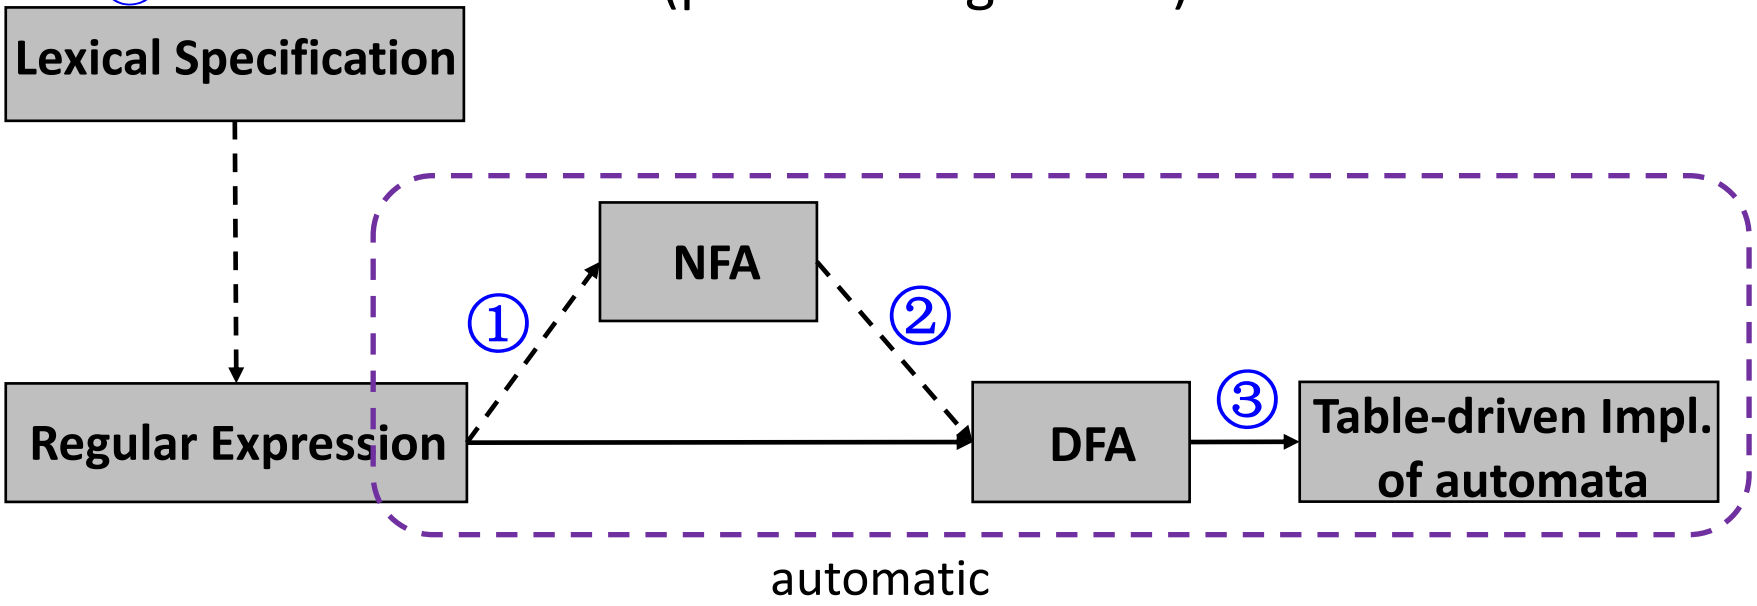
a	{ $action_1$ }
abb	{ $action_2$ }
a*b+	{ $action_3$ }

How to Match Keywords?[匹配关键字]

- Example: to recognize the following tokens
  - Identifiers: letter(letter|digit)*
  - Keywords: if, then, else
- **Approach 1**: make REs for keywords and place them before REs for identifiers so that they will take precedence
  - Will result in more bloated finite state machine
- **Approach 2**: recognize keywords and identifiers using same RE but differentiate using special keyword table
  - Will result in more streamlined finite state machine
  - But extra table lookup is required
- Usually approach 2 is more efficient than 1, but you can implement approach 1 in your projects for simplicity

The Conversion Flow[转换流程]

- Outline: RE → NFA → DFA → Table-driven Implementation
  - ③ Converting DFAs to table-driven implementations
  - ① Converting REs to NFAs (M-Y-T algorithm)
  - ② Converting NFAs to DFAs (subset construction)
  - ③' DFA minimization (partition algorithm)

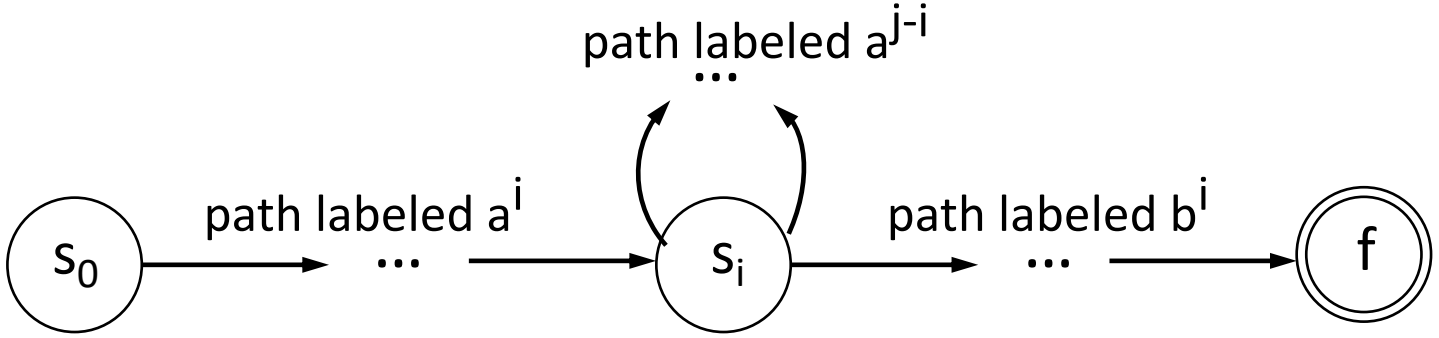


Beyond Regular Languages

- Regular languages are expressive enough for tokens
  - Can express identifiers, strings, comments, etc.
- However, it is the weakest (least expressive) language
  - Many languages are not regular
  - C programming language is not
    - The language matching braces "{{{...}}}" is also not
  - FA cannot count # of times char encountered
    - $L = \{a^n b^n \mid n \geq 1\}$
    - Crucial for analyzing languages with nested structures (e.g. nested for loop in C language)
- We need a more powerful language for parsing
  - Later, we will discuss context-free languages (CFGs)

RE/FA is NOT Powerful Enough

- $L = \{a^n b^n \mid n \geq 1\}$ is NOT a Regular Language
  - Suppose ***L*** were the language defined by regular expression
  - Then we could construct a DFA ***D*** with ***k*** states to accept ***L***
  - Since ***D*** has only ***k*** states, for an input beginning with more than ***k*** ***a***'s, ***D*** must enter some state twice, say s_i
  - Suppose that the path from s_i back to itself is labeled with a^{j-i}
  - Since $a^i b^i$ is in ***L***, there must be a path labeled b^i from s_i to an accepting state ***f***
  - But, there is also a path from s_0 through s_i to ***f*** labelled $a^i b^i$
  - Thus, ***D*** also accepts $a^i b^i$, which is not in ***L***, contradicting the assumption that ***L*** is the language accepted by ***D***



RE/FA is NOT Powerful Enough(cont.)

- $L = \{a^n b^n \mid n \geq 1\}$ is not a Regular Language
  - Proof → Pumping Lemma (泵引理)
  - FA does not have any memory (FA cannot count)
    - The above *L* requires to keep count of a's before seeing b's

- Matching parenthesis is not a RL
- Any language with nested structure is not a RL
  - if … if … else … else
- Regular Languages
  - Weakest formal languages that are widely used

Compilation Principle
编 译 原 理

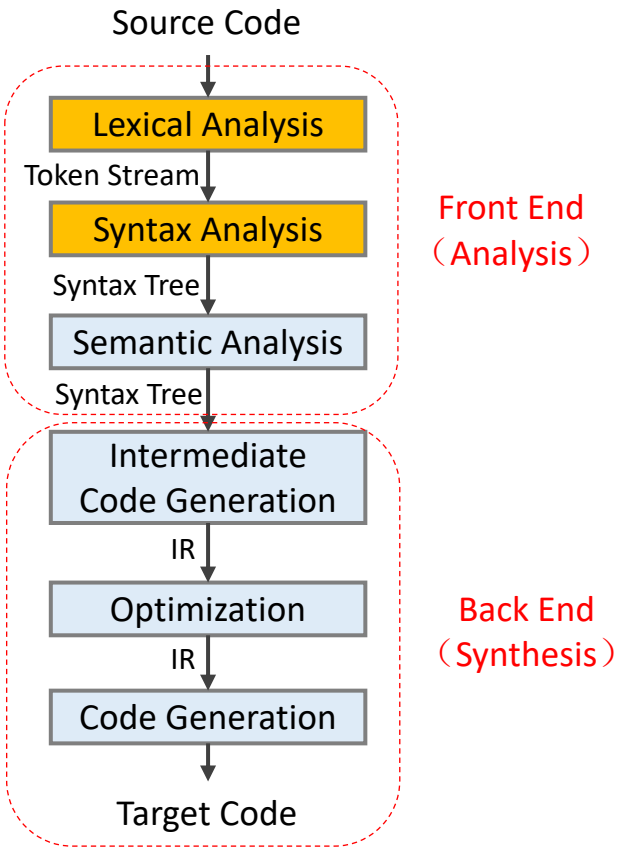
第4讲：语法分析(1)

张献伟

xianweiz.github.io

DCS290, 3/3/2022

Compilation Phases[编译阶段]



Syntax Analysis[语法分析]

- Second phase of compilation[第二阶段]
  - Also called as **parser**
- Parser obtains a string of tokens from the lexical analyzer[以token作为输入]
  - **Lexical analyzer** reads the chars of the source program, groups them into lexically meaningful units called **lexemes**
  - and produces as output **tokens** representing these lexemes
    - Token: <token name, attribute value>
  - Token names are used by parser for syntax analysis
    - tokens → parse tree/AST
- Parse tree[分析树]
  - Graphically represent the syntax structure of the token stream

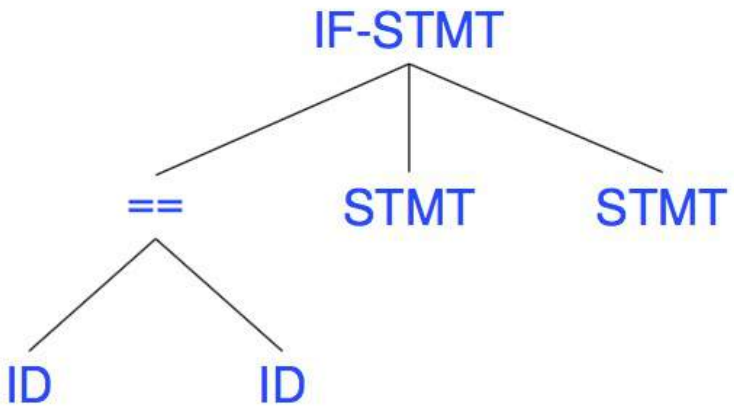
Parsing Example

- Input: if(x==y) … else …[源程序输入]

- Parser input (Lexical output)[语法分析输入]

  KEY(IF) ‘(‘ ID(x) OP(‘==‘) ID(y) ‘)’ … KEY(ELSE) …

- Parser output[语法分析输出]



Parsing Example (cont.)

- Example: <id, x> <op, *> <op, %>
  - Is it a valid token stream in C language? **YES**
  - Is it a valid statement in C language (x *%)? **NO**

- Not every string of tokens are valid
  - Parser must distinguish between valid and invalid token strings

- We need a method to describe what is valid string?
  - To specify the syntax of a programming language

How to Specify Syntax?

- How can we specify a syntax with nested structures?
  - Is it possible to use RE/FA?
  - L(Regular Expression) ≡ L(Finite Automata)

- RE/FA is not powerful enough
  - $L = \{a^n b^n \mid n \geq 1\}$ is not a Regular Language

- Example: matching parenthesis: # of '(' == # of ')'
  - (x+y)*z ✓
  - ((x+y)+y)*z ✓
  - (...(((x+y)+y)+y)...) ✓
  - ((x+y)+y)+y)*z ✗

What Language Do We Need?

- C-language syntax: **Context Free Language** (CFL)[上下文无关语言] e.g., 'else' is always 'else', wherever you place it
  - A broader category of languages that includes languages with nested structures
- Before discussing CFL, we need to learn a more general way of specifying languages than RE, called **Grammars**[文法]
  - Can specify both RL and CFL
  - and more ...
- Everything that can be described by a regular expression can also be described by a grammar
  - Grammars are most useful for describing nested structures

Concepts

- **Language**[语言]
  - Set of strings over alphabet
    - *String*: finite sequence of symbols
    - *Alphabet*: finite set of symbols
- **Grammar**[文法]
  - To systematically describe the syntax of programming language constructs like expressions and statements
- **Syntax**[语法]
  - Describes the proper form of the programs
  - Specified by grammar

Grammar[文法]

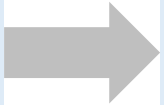
- Formal definition[形式化定义]: 4 components **{T, N, s, δ}**
- ***T***: set of terminal symbols[终结符]
  - Basic symbols from which strings are formed
  - Essentially tokens - leaves in the parse tree
- ***N***: set of non-terminal symbols[非终结符]
  - Each represents a set of strings of terminals – internal nodes
  - E.g.: declaration, statement, loop, ...
- **s**: start symbol[开始符号]
  - One of the non-terminals
- ***σ***: set of productions[产生式]
  - Specify the manner in which the terminals and non-terminals can be combined to to form strings
  - "LHS → RHS": left-hand-side produces right-hand-side

Grammar (cont.)

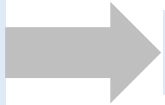
- Usually, we can only write the σ[简写]

- Merge rules sharing the same LHS[规则合并]
  - $\alpha \rightarrow \beta_1, \alpha \rightarrow \beta_2, \ldots, \alpha \rightarrow \beta_n$
  - $\alpha \rightarrow \beta_1 \mid \beta_2 \mid \ldots \mid \beta_n$

G = ({id, +, *, (,)} , {E}, E, P)
P = { E → E + E,
E → E * E,
E → (E),
E → id }



G: E → E + E,
E → E * E,
E → (E),
E → id }



E → E + E | E * E | (E) | id
